## RESUMO

Nós tratamos um problema centróide discreto composto de duas firmas, líder e seguidora, competindo para atender a demanda de clientes em um determinado mercado. A demanda de cada cliente pode ser totalmente atendida por uma das firmas ou não atendida de acordo com uma regra de distância. A líder localiza suas facilidades sobre um grafo sabendo que a seguidora reagirá fazendo o mesmo e deseja maximizar sua fatia do mercado no pior caso. O número de facilidades localizadas pelas duas firmas respeita uma restrição orçamentária. O problema consiste em decidir onde a líder localiza suas facilidades. Este problema é $\sum_{2}^{\mathrm{p}}$-difícil. Apesar disso, nós apresentamos uma formulação por programação inteira com um número polinomial de variáveis e um número exponencial de restrições. Nós reportamos diversos experimentos variando o número de clientes e facilidades e os valores de orçamento. Nossos resultados mostram que nosso método resolve em torno de uma hora instâncias com até 225 clientes, 150 facilidades com as firmas podendo localizar até 7 facilidades.

Área Principal: Otimização

#### Abstract

We deal with a discrete centroid problem composed of two noncooperative firms, a leader and a follower, competing to serve the demand of customers from a given market. Each customer's demand can be totally served by one of the two facilities or not served according to a distance rule. The leader places it facilities on a graph knowing that the follower will react by doing the same and wants to maximize it market share at the worst case. The number of facilities placed by the two firms is under a budget constraint. The problem consists of deciding where the leader places its facilities. This problem is a $\sum_{2}^{\mathrm{p}}$-hard one. In spite of it, we present an integer programming formulation with polynomially many variables and exponentially many constraints. Moreover, we report several experiments with different number of customers and applicant facilities and different values of budgets. Our results show that our method requires less than 1 hour to solve instances with up to 225 customers and 150 applicant facilities where the firms could place up to 7 facilities.

KEY WORDS. Leader-Follower problems, Competitive Facility Location, Game Theory.

## Main area: Optimization

## 1 Introduction

In competitive location models, two or more noncooperative firms compete to provide customers from a given market. Each customer is partially, totally or not served by facilities placed by the firms according to a customer choice rule. Different objective functions can be pursued by each firm when it decides where to place its facilities. For example, they might aim to maximize their own market share, their own profit, their own number of customers served, among others. When the decision is made sequentially, the model is called sequential competitive location model. A review of competitive location models and of sequential ones can be found in Eiselt and Laporte (1989), Friesz et al. (1988), Eiselt et al. (1993), Eiselt and Laporte (1997) and Kress and Pesch (2011).

There is a special class of sequential competitive location problems composed of two firms, leader and follower. The leader must to decide where to place its facilities knowing that the follower will react by doing the same. The problems of deciding where the leader and the follower place their facilities are respectively called centroid and medianoid problems.

We deal in this paper with a discrete centroid problem where the number of facilities placed by both the leader and the follower is under a budget constraint. Each customer's demand is fully served by the closest facility placed by either the leader or the follower if this facility is lying with a threshold distance. Otherwise, this customer is not served. The leader aims to maximize it market share at the worst case. The worst case happens when the follower places its facilities aiming to steal the maximum possible demand from the leader. We call this problem the worst case budget constrained centroid problem, or simply, WCBC centroid problem.

We found in the literature just one paper that deals specifically with the WCBC centroid problem proposed by Plastria and Vanhaverbeke (2008). The authors proposed an integer programming model for the WCBC centroid problem for the particular case where the follower places a single facility. Besides the authors also proposed models for more two cases. In the first one, the leader aims to minimize it regret while in the second one, both the leader and the follower aim to maximize their market share.

In this paper, we propose a branch-and-cut algorithm for the WCBC centroid problem. Our algorithm is based on the best exact one for the ( $r \mid p$ )-centroid problem (Hakimi, 1983) proposed by Roboredo and Pessoa (2011). The previous problem is $\sum_{2}^{\mathrm{p}}$-hard (Noltemeier et al., 2007) and is similar to the one dealt in this paper with three differences. The first one is that both the leader and the follower have a predetermined number of facilities to place, the second one is that there is not the threshold distance while the third one is that both the leader and the follower aim to maximize their market share.

As any instance of the $(r \mid p)$-centroid problem is easily converted to a instance of the WCBC centroid problem, this problem is also $\sum_{2}^{\mathrm{p}}$-hard. Hence, that problem turns out to be harder than any optimization problem whose decision version is in $N P$. The hardness of that problem comes from the fact that evaluating a single leader's strategy requires to solve an $N P$-hard problem to decide the follower's strategy which minimizes the market share of the leader. Fortunately, this problem often spends less than one second for instances with 100 customers and 100 applicant facilities by solving an Integer Programming (IP) model.

The integer programming (IP) formulation proposed in this paper has polynomially many variables and exponentially many constraints. One should note that, since the problem is $\sum_{2}^{\mathrm{p}}$-hard, neither a polynomial formulation nor a formulation where all constraints can be separated in polynomial time is possible unless $N P=\sum_{2}^{\mathrm{p}}$. Hence, the constraints are separated during the optimization either using a greedy heuristic or exactly solving an IP model. We test our method on a group of instances randomly generated in the same way as in Plastria and Vanhaverbeke (2008). Besides we increase the difficult of the instances by increasing the budgets of the leader and the follower.

This paper is divided as follows. In Section 2, we define the problem and present an IP model for it. In section 3, we define the separation problem for the only exponential family of constraints used in our formulation, and present an IP model and a greedy heuristic for it. In section 4, we report our experiments. Finally, in section 5, we summarize our conclusions.

## 2 The problem

The problem is formally defined as follows: Consider two nooncooperative firms (leader and follower). To place a facility $i$, it is necessary to spent a fixed cost $f_{i}$. The budgets of the leader and the follower are denoted respectively by $B_{l}$ and $B_{f}$. The leader has to place facilities on an arena knowing that the follower will do the same. The arena is a graph $G=(V, E)$ where each vertex $v \in V$ is a customer and an applicant facility of either the leader or the follower. As a result, $V$ is composed of the three subsets, $J, L$ and $F$, where $J$ is the set of customers and $L$ and $F$ are the set of applicant facilities for the leader and the follower respectively. The edge set $E$ of $G$ has an edge $e=(i, j)$ for each $i \in L$ and $j \in J$ and for each $i \in F$ and $j \in J$, with an associated distance $d_{i j}$. Each customer's demand $w_{j}$ is totally served by the closest facility placed by either the leader or the follower if this facility is lying with a threshold distance $\delta_{j}$. Ties are broken in favor of the follower's facilities, and ties between facilities of the same firm are broken arbitrarily. The leader aims to obtain the maximum market share at the worst case. The worst case happens when the follower places its facilities aiming to steal the maximum possible demand from the leader. The discrete worst case budget constrained centroid problem consists of deciding where the leader places its facilities.

We show that, besides its complexity, the discrete WCBC centroid problem admits an IP formulation with polynomially many variables and exponentially many constraints. Let the binary variables $x_{i}$ indicate whether the leader places a facility at the location $i$ and the continuous variables $y_{i j}$ indicate whether the leader places the facility $i$ trying to dominate the customer $j$. Finally, let the integer variable $z$ give the total leader's market share at the worst case. Let $S$ be the set of strategies for the follower. It means that each $S_{0} \in S$ is a set of facilities under the budget constraint placed by the follower. The complete model is below.

$$
\begin{equation*}
\max \quad z \tag{1}
\end{equation*}
$$

subject to

$$
\begin{align*}
\sum_{i \in L} f_{i} x_{i} \leq B_{l} &  \tag{2}\\
y_{i j} \leq x_{i}, & \forall j \in J, \forall i \in L  \tag{3}\\
\sum_{i \in L} y_{i j}=1, & \forall j \in J  \tag{4}\\
z \leq \sum_{j \in J} w_{j} y_{i j}, & \forall S_{0} \in S  \tag{5}\\
\sum_{i \in L \mid d_{i j}<\min \left\{d_{k j} \mid k \in S_{0}\right\} \wedge d_{i j} \leq \delta_{j}} &  \tag{6}\\
y_{i j} \geq 0, & \forall i \in L, \forall j \in J  \tag{7}\\
x_{i} \in\{0,1\}, & \forall i \in L .
\end{align*}
$$

The objective function (1) maximizes the total market share of the leader at the worst case. The first constraint (2) is a budget one for the facilities placed by the leader. Constraints (3) ensure the consistency between the variables $x_{i}$ and $y_{i j}$. The set of constraints (4) indicates that for each customer $j$, exactly one facility $i$ is the leader's facility nearest to $j$. Finally, (5) ensures that, for each possible strategy $S_{0} \in S$ for the follower, the total leader's market share at the worst case $z$ is given by the total demand associated to customers that are nearer to a leader's facility than to any
location $k \in S_{0}$ if this leader's facility is lying with the threshold distance $\delta_{j}$. Note that depending of the follower's budget $B_{f}$, (5) is composed of an exponential number of constraints. Hence, it is necessary to solve the separation problem associated to (5) in order to include in the formulation only the necessary constraints.

## 3 Separation Problem

In this section, we define the separation problem and two separation procedures for the constraints given by (5). Although we do not know whether this problem is $N P$-hard, we remark (1)-(7) result in a valid formulation for the discrete WCBC centroid problem. Hence, a polynomial algorithm for the exact separation of (5) would imply that the decision version of the discrete WCBC centroid problem belongs to $N P$, and thus, that $N P=\sum_{2}^{\mathrm{p}}$.

The separation problem of (5) is defined as follows. Given a relaxed solution $(\bar{z}, \bar{x}, \bar{y}) \in$ $\mathbb{R} \times[0,1]^{|L|} \times[0,1]^{|L| \times|J|}$ that satisfies (2), (3), (4) and some of the constraints (5), the separation problem consists of finding the strategy $S_{0} \in S$ that maximizes the violation of (5). For that, $S_{0}$ should to minimize

$$
\begin{equation*}
\sum_{j \in J} w_{j} \sum_{i \in L \mid d_{i j}<\min \left\{d_{k j} \mid k \in S_{0}\right\} \wedge d_{i j} \leq \delta_{j}} \bar{y}_{i j} \tag{8}
\end{equation*}
$$

For each customer $j$, let $k_{j}^{*}=\arg \min _{k \in S_{0}}\left\{d_{k j}\right\}$. Then, (8) can be rewritten as

$$
\begin{equation*}
\sum_{j \in J} w_{j} \sum_{i \in L \mid d_{i j} \leq d_{k_{j}^{*} j} \wedge d_{i j} \leq \delta_{j}} \bar{y}_{i j} \tag{9}
\end{equation*}
$$

Next, we show an IP formulation for this problem. Let the binary variable $s_{k}$ indicate that $k \in S_{0}$. Let also the binary variables $t_{j k}$ indicate that $k$ is the facility of $S_{0}$ that is closest to the customer $j$. The complete formulation is the following:

$$
\begin{equation*}
\min \sum_{j \in J} \sum_{k \in F}\left(w_{j} \sum_{i \in L \mid d_{i j} \leq d_{k j} \wedge d_{i j} \leq \delta_{j}} \bar{y}_{i j}\right) \times t_{j k} \tag{10}
\end{equation*}
$$

subject to

$$
\begin{align*}
\sum_{k \in F} f_{k} s_{k} \leq B_{f} &  \tag{11}\\
t_{j k} \leq s_{k}, & \forall j \in J, \forall k \in F  \tag{12}\\
\sum_{k \in F} t_{j k}=1, & \forall j \in J  \tag{13}\\
t_{j k} \in\{0,1\}, & \forall k \in F, \forall j \in J  \tag{14}\\
s_{k} \in\{0,1\}, & \forall k \in F . \tag{15}
\end{align*}
$$

The value of the objetive function (10) is equivalent to the sum (9). Constraint (11) ensures that $S_{0}$ respects the follower's budget. Constraints (12) ensure the consistency between the variables $t_{j k}$ and $s_{k}$. Constraints (13) ensure that, for each customer $j$, there is only one facility $k \in S_{0}$ closest to this one.

We also propose a greedy heuristic for the separation problem. This heuristic is used to efficiently find some violated cuts avoiding some IP optimizations. To describe this heuristic, we
recall that the separation problem is to find the strategy $S_{0} \in S$ that minimize (8). The heuristic first greedily constructs the strategy $S_{0}$ by choosing facilities one at a time as follows. At each iteration, it chooses the facility that causes the maximum ratio between the diminution in the value of the terms of (8) and its fixed cost.

Our exact algorithm is built on the top of the branch-and-cut algorithm implemented by the CPLEX solver using the model given by (1), (2), (3), (4), (6), and (7). The constraints (5) are added through the cut callback provided by the solver by applying the separation procedures described before. All the branch-and-bound tree management is performed by CPLEX.

In order to speed up our method, the cuts are separated in the following way. We define the value of a parameter $\epsilon$ and while the gap is greater than $\epsilon$, we separate cuts associated to the constraints (5) for any solution. Otherwise, when the gap is smaller or equal $\epsilon$, the cuts are separated only for integer solutions (for that, we use only the IP based separation). We define the a value of $\epsilon$ according to the values of $B_{l}$ and $B_{f}$ where the higher the values of $B_{l}$ and $B_{f}$, the lower the value of $\epsilon$.

Based on the leader's optimal solution given by solving (1)-(7), we also obtain the maximum demand that the follower steals from the leader. That value can be obtained by solving the separation problem (10)-(15) since that problem aims to find the follower's strategy that minimizes the demand served by the leader.

## 4 Computational experiments

In this section, we present computational results of our method. We use the CPLEX 12.1 and all the tests are carried out in a 2.31 GHz PC AMD Phenom X4 9600 with 3 Gb of RAM. We tested our method on randomly generated instances as in Plastria and Vanhaverbeke (2008). For those instances, the coordinates of customers and facilities are randomly distributed on square grids, where each grid cell with integer coordinates is both a customer and a applicant facility for either the leader or the follower. Hence there are not common applicant facilities for the leader and for the follower. The applicant facilities for the follower (set $F$ ) is composed of those cells whose the sum of the coordinates is a multiple of 3 while the applicant facilities for the leader (set $L$ ) consists of all the other cells, so approximately $|L| \approx 2|F|$. We assumed to be euclidean the distances between customers and facilities. The customer demands $w_{j}$ and the fixed costs $f_{i}$ were randomly generated, uniformly distributed integer in the ranges $[50,250$ ] and $[5,10]$ respectively. We set the following values for the budgets $B_{l}$ and $B_{f}: 15$ and 25 . For all the instances tested, we considered $B_{l}=B_{f}$. The maximum travel distances $\delta_{j}$ tested was $1,2, \sqrt{8}, 3, \sqrt{13}, 4$ and $+\infty$ where we considered that the maximum travel distances are the same for each customer. We considered 6 types of square grids: $5 \times 5,7 \times 7,10 \times 10,12 \times 12,15 \times 15$ and $17 \times 17$. We set $\epsilon=0.15$ for instances with $B_{l}=B_{f}=15$ and $B_{l}=B_{f}=25$ and set $\epsilon=0.12$ for instances with $B_{l}=B_{f}=35$

Tables 1, 2 and 3 show results of our method for $B_{l}=B_{f}=15, B_{l}=B_{f}=25$ and $B_{l}=B_{f}=35$ respectively. The following headers are used for the columns. Columns Grid size, $\delta_{j}$, $|J|,|L|,|F|$ indicate the instance characteristics, Sum of demands indicates the sum $\sum_{j \in J} w_{j}$, \#Leader demand,\#Follower demand and \#Lost demand indicate respectively the total demand served by the leader, the follower and the total demand not served at the worst case, \#Stolen demand indicates the total demand served by the follower but it was served by the leader before the follower place its facilities, \#Cuts, \#Nodes and Time(s) total indicates respectively the total number of cuts generated, the total number of nodes created by the branch-and-cut tree and the total CPU time in seconds consumed by the complete branch-and-cut algorithm.

Note in tables 1, 2 and 3 that the total leader's market share at the worst case not decreases as the maximum travel distance or the budgets increase. Another interesting observation is that the total number of cuts and nodes is relatively small even for large instances illustrating the robustness of our method.

Table 1: Statistics of our method for $B_{l}=B_{f}=15$

| Grid <br> size | $\delta_{j}$ |  |  |  | Sum of demands | \#Leader demand | \#Follower demand | $\begin{array}{r} \text { \#Lost } \\ \text { demand } \end{array}$ | \#Stolen demand | \#Cuts <br> Total | \#B\&B Nodes | $\begin{array}{r} \text { \#Time(s) } \\ \text { Total } \\ \hline \end{array}$ |

For all the types of budgets tested, the total demand served by the leader and the follower are similar for instances with large grids $(12 \times 12,15 \times 15$ and $17 \times 17)$ leading us to think that for larger grid sizes, it also would happen.

Regarding the computational time, we observe that instances with grid size up to $12 \times 12$, it was necessary less than 1 hour to solve. On the other hand larger instances are harder for our method. For example, it was necessary almost 76000 seconds to solve the instance with $B_{l}=B_{f}=25$, grid size $17 \times 17$ and $\delta_{j}=2$. For this reason, we did not test instances with $B_{l}=B_{f}=35$ and grid size $17 \times 17$.

## 5 Conclusions

In this paper, we presented a branch-and-cut algorithm for the discrete WCBC centroid problem using a new MIP formulation with polynomially many variables and exponentially many constraints. We also presented exhaustive experiments that proved the efficiency and robustness of our method. As future researches, we intend to generalize the others two cases proposed in Plastria and Vanhaverbeke (2008). The first one is when the leader wants to minimize it regret while in the second one, both the leader and the follower want to maximize their own market share.
